def add(a): b = a + 1print(a, "if you add one", b) return(b) The figure below illustrates the terminology: **Parameters** keyword name We can obtain help about a function: # Get a help on add function help(add) Help on function add in module main : add(a) We can call the function: # Call the function add() add (1) 1 if you add one 2 Out[3]: 2 If we call the function with a new input we get a new result: # Call the function add() In [4]: add (2) 2 if you add one 3 Out[4]: 3 We can create different functions. For example, we can create a function that multiplies two numbers. The numbers will be represented by the variables a and b: # Define a function for multiple two numbers def Mult(a, b): c = a * b return(c) print('This is not printed') result = Mult(12,2)print(result) 24 The same function can be used for different data types. For example, we can multiply two integers: # Use mult() multiply two integers Mult(2, 3)Note how the function terminates at the return statement, while passing back a value. This value can be further assigned to a different variable as desired. The same function can be used for different data types. For example, we can multiply two integers: Two Floats: # Use mult() multiply two floats Mult(10.0, 3.14) Out[7]: 31.400000000000002 We can even replicate a string by multiplying with an integer: # Use mult() multiply two different type values together Mult(2, "Michael Jackson ") Out[8]: 'Michael Jackson Michael Jackson ' **Variables** The input to a function is called a formal parameter. A variable that is declared inside a function is called a local variable. The parameter only exists within the function (i.e. the point where the function starts and stops). A variable that is declared outside a function definition is a global variable, and its value is accessible and modifiable throughout the program. We will discuss more about global variables at the end of the lab.

IBM Developer

SKILLS NETWORK

Welcome! This notebook will teach you about the functions in the Python Programming Language. By the end of this lab, you'll know the

A function is a reusable block of code which performs operations specified in the function. They let you break down tasks and allow you to

You can define functions to provide the required functionality. Here are simple rules to define a function in Python:

• Functions blocks begin def followed by the function name and parentheses ().

• There is a body within every function that starts with a colon (:) and is indented.

The statement return exits a function, optionally passing back a value.

• You can also define parameters inside these parentheses.

First function example: Add 1 to a and store as b

• You can also place documentation before the body.

• There are input parameters or arguments that should be placed within these parentheses.

An example of a function that adds on to the parameter a prints and returns the output as b:

Functions in Python

After completing this lab you will be able to:

Understand functions and variablesWork with functions and variables

Functions in Python

Table of Contents

Variables

Global variablesScope of a Variable

Quiz on Loops

Functions

Pre-defined functions

Collections and Functions

reuse your code in different programs.

There are two types of functions:

Pre-defined functionsUser defined functions

What is a Function?

Function Definition

c = a * a + b

return(c)

c=1

Local variable b

The labels are displayed in the figure:

print(a, "if you square + 1", c)

def square(a): Formal parameter

Square the input add add 1

Local variable

We can call the function with an input of **3**:

Makes function call and return function a y

We can call the function with an input of **2** in a different manner:

If there is no return statement, the function returns None. The following two functions are equivalent:

Define functions, one with return value None and other without return value

Printing the function after a call reveals a **None** is the default return statement:

Create a function con that concatenates two strings using the addition operation:

[Tip] How do I learn more about the pre-defined functions in Python?

We will be introducing a variety of pre-defined functions to you as you learn more about Python. There are just too many functions, so there's no way we can teach them all in one sitting. But if you'd like to take a quick peek, here's a short reference card for some of the

Consider the two lines of code in **Block 1** and **Block 2**: the procedure for each block is identical. The only thing that is different is the

We can replace the lines of code with a function. A function combines many instructions into a single line of code. Once a function is

defined, it can be used repeatedly. You can invoke the same function many times in your program. You can save your function and use it in another program or use someone else's function. The lines of code in code **Block 1** and code **Block 2** can be replaced by the following

This function takes two inputs, a and b, then applies several operations to return c. We simply define the function, replace the instructions

with the function, and input the new values of a1, b1 and a2, b2 as inputs. The entire process is demonstrated in the figure:

Directly enter a number as parameter

print('Michael Jackson')

print('Michael Jackson')

See what functions returns are

Define the function for combining strings

commonly-used pre-defined functions: Reference

Functions Make Things Simple

c1 = a1 + b1 + 2 * a1 * b1 - 1

a and b calculation block2

c2 = a2 + b2 + 2 * a2 * b2 - 1

In [20]: # Make a Function for the calculation above

c = a + b + 2 * a * b - 1

c1=a1+b1+2*a1*b1-1

Code Blocks 1 and Block 2 can now be replaced with code Block 3 and code Block 4.

There are many pre-defined functions in Python, so let's start with the simple ones.

Using if/else Statements and Loops in Functions

The return() function is particularly useful if you have any IF statements in the function, when you want your output to be dependent

album_ratings = [10.0, 8.5, 9.5, 7.0, 7.0, 9.5, 9.0, 9.5]

if(c1<0): c1=0

else: c1=5

Block 3:

b1 = 5

Block 4:

b2 = 0

c2

c1 = Equation(a1, b1)

c2 = Equation(a2, b2)

The print() function:

print(album_ratings)

sum(album_ratings)

len(album_ratings)

on some condition:

else:

print(x)

1

the man abc

Function example

Pre-defined functions

Build-in function print()

[10.0, 8.5, 9.5, 7.0, 7.0, 9.5, 9.0, 9.5]

The sum() function adds all the elements in a list or tuple:

The len() function returns the length of a list or tuple:

def type_of_album(artist, album, year_released):

x = type_of_album("Michael Jackson", "Thriller", 1980)

We can use a loop in a function. For example, we can print out each element in a list:

Setting default argument values in your custom functions

threshold for what we consider to be a good rating? Perhaps by default, we should have a default rating of 4:

You can set a default value for arguments in your function. For example, in the isGoodRating() function, what if we wanted to create a

So far, we've been creating variables within functions, but we have not discussed variables outside the function. These are called global

It's because all the variables we create in the function is a **local variable**, meaning that the variable assignment does not persist outside the

The scope of a variable is the part of that program where that variable is accessible. Variables that are declared outside of all function

definitions, such as the myFavouriteBand variable in the code shown here, are accessible from anywhere within the program. As a result, such variables are said to have global scope, and are known as global variables. myFavouriteBand is a global variable, so it is accessible from within the getBandRating function, and we can use it to determine a band's rating. We can also use it outside of the function, such

Take a look at this modified version of our code. Now the myFavouriteBand variable is defined within the getBandRating function. A variable that is defined within a function is said to be a local variable of that function. That means that it is only accessible from within the

function. However, we can no longer print myFavouriteBand outside our function, because it is a local variable of our getBandRating

Finally, take a look at this example. We now have two myFavouriteBand variable definitions. The first one of these has a global scope, and the second of them is a local variable within the getBandRating function. Within the getBandRating function, the local variable

getBandRating function, the getBandRating s local variable is not defined, so the myFavouriteBand variable we print is the global

takes precedence. Deep Purple will receive a rating of 10.0 when passed to the getBandRating function. However, outside of the

function in which it is defined. Our getBandRating function will still work, because myFavouriteBand is still defined within the

print(artist, album, year_released)

if year_released > 1980:
 return "Modern"

return "Oldie"

Michael Jackson Thriller 1980

Print the list using for loop

for element in the_list:
 print(element)

Implement the printlist function

PrintList(['1', 1, 'the man', "abc"])

Example for setting param with default value

Test the value with default value and with input

print("this album sucks it's rating is", rating)

print("this album is good its rating is", rating)

def isGoodRating(rating=4):
 if(rating < 7):</pre>

this album sucks it's rating is 4 this album is good its rating is 10

Let's try to see what printer1 returns:

Example of global variable

internal var1 = artist

try runningthe following code

print(artist, "is an artist")

We got a Name Error: name 'internal_var' is not defined . Why?

But there is a way to create **global variables** from within a function as follows:

artist = "Michael Jackson"
def printer1(artist):

#printer1(internal var1)

Michael Jackson is an artist

artist = "Michael Jackson"

global internal_var

Michael Jackson is an artist Whitney Houston is an artist

Scope of a Variable

internal_var= "Whitney Houston"
print(artist,"is an artist")

as when we pass it to the print function to display it:

if bandname == myFavouriteBand:

print("AC/DC's rating is:", getBandRating("AC/DC"))

print("My favourite band is:", myFavouriteBand)

function; it is only defined within the getBandRating function:

print("AC/DC's rating is: ", getBandRating("AC/DC"))

print("My favourite band is", myFavouriteBand)

print("Deep Purple's rating is: ", getBandRating("Deep Purple"))

Example of global variable and local variable with the same name

print("Deep Purple's rating is: ",getBandRating("Deep Purple"))

When the number of arguments are unknown for a function, They can all be packed into a tuple as shown:

def printAll(*args): # All the arguments are 'packed' into args which can be treated like a tuple

Functions can be incredibly powerful and versatile. They can accept (and return) data types, objects and even other functions as

Note how the changes made to the list are not limited to the functions scope. This occurs as it is the lists **reference** that is passed to the function - Any changes made are on the original instance of the list. Therefore, one should be cautious when passing mutable objects into

Congratulations, you have completed your first lesson and hands-on lab in Python. However, there is one more thing you need to do. The Data Science community encourages sharing work. The best way to share and showcase your work is to share it on GitHub. By sharing your notebook on GitHub you are not only building your reputation with fellow data scientists, but you can also show it off when applying for a job. Even though this was your first piece of work, it is never too early to start building good habits. So, please read and follow this article

Change Description

Under What is a function, added code/text to further demonstrate the functionality of the return statement

Under Global Variables, modify the code block to try and print 'internal_var' - So a nameError message can be

print("Deep Purple's rating is:",getBandRating("Deep Purple"))

Example of global variable

def getBandRating(bandname):

return 10.0

return 0.0

AC/DC's rating is: 10.0 Deep Purple's rating is: 0.0 My favourite band is: AC/DC

In [34]: # Example of local variable

else:

def getBandRating(bandname):
 myFavouriteBand = "AC/DC"

return 10.0

return 0.0

AC/DC's rating is: 10.0 Deep Purple's rating is: My favourite band is AC/DC

variable, which has a value of AC/DC:

myFavouriteBand = "AC/DC"

def getBandRating(bandname):

return 10.0

return 0.0

AC/DC's rating is: 0.0

Deep Purple's rating is: 10.0 My favourite band is: AC/DC

Collections and Functions

for argument in args:
 print(argument)
#printAll with 3 arguments

#printAll with 4 arguments

def printDictionary(**args):
 for key in args:

arguements. Consider the example below:

list.append("Three")
list.append("Four")

No of arguments: 3

No of arguments: 4

Country : Canada
Province : Ontario
City : Toronto

def addItems(list):

myList = ["One", "Two"]

Out[38]: ['One', 'Two', 'Three', 'Four']

Quiz on Functions

def div(a, b):
 return(a/b)

def con(a, b):

con(3, 2)

return(a + b)

► Click here for the solution

con(['a', 1], ['b', 1])

['a', 1, 'b', 1]
